28 This paper investigates improvement possibilities in the cleaning operations undertaken  
29 at an industrial brewery. Experiments were performed on a bench scale cleaning rig  
30 which was designed to simulate ‘real life’ cleaning conditions of a clean-in-place (CIP)  
31 set in the brewery. The rig was used to clean consistently fouled coupons using difficult  
32 soils from the brewery. The objective of the experiments was to determine the reduction  
33 in effective cleaning performance with varied levels of Na<sub>2</sub>CO<sub>3</sub> in the detergent from  
34 NaOH degradation and the maximum level that may be present before cleaning quality  
35 is impacted. The shear force of the cleaning fluid across the surface of the coupon was  
36 also varied to determine the impact on cleaning performance. Data collected from these  
37 offline measurements has been used to predict the end point of the detergent usage  
38 based on cost optimisation within the empirically determined limits. The results show  
39 that the NaOH detergent usage can be extended while achieving the same time to clean  
40 without impacting the cleaning quality and preventing premature disposal. This will  
41 provide an increased confidence level when cleaning fermenters with NaOH. It will  
42 also reduce cleaning costs and benefit the environment by reducing chemical effluent  
43 and minimising water consumption.

49 Understanding of cleaning chemical effectiveness in brewery cleaning

50 Increasing the time of use of cleaning fluids in a brewery

51

52

## 53 **Introduction**

54 Effective process cleaning in a brewery is an essential business requirement to achieve  
55 consistently high standards of product quality and hygiene but it can be a costly  
56 undertaking. Current Clean-in-Place (CIP) systems can exhibit lengthy cleaning times  
57 causing production down time and lost production capacity, increased effluent  
58 treatment and higher utility costs. Ineffective cleaning of equipment in the brewing  
59 industry is detrimental to the end product quality with respect to taste, appearance and  
60 conformance to health and safety legislation. Hence the length of clean is increased and  
61 specified to accommodate uncertainty and variation in cleaning behaviour so that such  
62 issues do not arise. Variations in cleaning time occur as a consequence of product  
63 changeover, where one product requires a more vigorous clean than the other and for  
64 the same product general batch to batch variation, where the cleaning parameters may  
65 meet the requirements of one batch but it may not be sufficient to clean another batch.

66 The literature associated with cleaning and CIP improvement considers scales from  
67 cleaning fluid - soil –surface interaction to how this impacts on the behaviour of large  
68 process plant. A review of process cleaning highlighting the challenges facing industry  
69 can be found in Wilson (2005), with a more recent review by Goode et al (2013). At  
70 the surface scale Kaye et al (1995) investigated the effect of jet cleaning on a soiled  
71 surface. They highlighted the nature of surface removal by jet cleaning and the  
72 importance of optimizing operating parameters such as turbulence and jet velocity over  
73 the surface to ensure effective cleaning. Palabiyik *et al* (2015) recently similarly  
74 considered the mechanisms of soil removal and how shear rate could be varied during  
75 the clean to minimise the use of cleaning fluid to deliver the most effective clean. Cleaning  
76 fluid temperature and velocity were varied to accommodate the changes in the  
77 mechanisms of removal. Lewis et al (2012) considered the cleaning of biofilms from  
78 membranes and in studies on yeast observed the relationship between cleaning fluid  
79 velocity and thus shear stress and biofilm removal. A more quantitative approach to  
80 assessing the effectiveness of process cleaning was taken by Köhler et al (2015) who  
81 sought to optimise the cleaning parameters when using a moving jet to clean a Xanthan  
82 gum soiled surface. They considered time to clean, fluid used, energy used and overall  
83 cost as metrics. It was observed that a global optimum of all four metrics cannot be  
84 achieved and a balance is required as specific circumstances dictate. In their studies  
85 they considered the design properties of the nozzle (nozzle diameter, gauge pressure  
86 and jet moving speed) and the velocity of the fluid. This work was expanded on further  
87 by Wilson et al (2015) who developed a mathematical model to provide predictive  
88 performance of the system consider by Köhler and achieved good agreement with  
89 experimental results. The need to improve cleaning systems and the requirement for  
90 more informative measurements in attempts to optimize cleaning when natural  
91 variation occurs was considered by Van Asselt et al (2002) who highlighted the benefits  
92 of conductivity measurements in dairy process cleaning.

93 When considering the addition of chemicals to enhance cleaning, Eide et al (2003)  
94 consider the optimization of cleaning chemical choice demonstrating in their case the

95 enhanced performance provided by sodium hydroxide. Christian and Fryer (2006)  
96 studied the impact of changing Sodium Hydroxide concentration and variations in fluid  
97 flow to clean whey protein. They observed the need to have long enough exposure of  
98 the soil to cleaning agent at sufficient concentration to cause the soil to swell before  
99 removal. Constant flow was not necessary and therefore cleaning chemical usage could  
100 be reduced. Fryer et al (2011) considered the impact and predictability of cleaning as  
101 scale of operation changes and whether predictive performance could be achieved  
102 across soils. They observed that for certain soil types predictive performance could be  
103 achieved but for others complex relationships existed. Considering brewery cleaning in  
104 particular several publications have highlighted the high costs associated with cleaning  
105 and options for improvement. For instance, Pettigrew et al (2015) in addition to  
106 describing the brewery process and cleaning costs, developed a simulation of the  
107 brewery CIP system and formulated an optimisation approach based on the use of an  
108 object oriented Petri net to improve water usage in part of the brewery. Goode et al  
109 (2010) investigated the optimisation of brewery cleaning with respect to cleaning fluid  
110 temperature and cleaning agent concentration and suggested that lower temperature  
111 cleaning could be effective.

112 While such scientific studies grow fundamental understanding, practical considerations  
113 remain to be addressed. Sodium hydroxide is commonly used as a cleaning detergent  
114 in the brewing industry and is known to effectively clean brewery soils but its use is  
115 not without problems. These include; i) the level of cleanliness of the equipment  
116 surfaces is unknown before or during the clean due to measurement limitations, ii)  
117 formation of sodium carbonate in the caustic solution, which reduces the cleaning  
118 power and can sometimes result in chemical cleans which are not within specification  
119 being performed. A cautious approach however causes excessive and expensive  
120 disposal of cleaning chemicals, iii) Uncertainty about the effectiveness of the cleans  
121 provided by different types of spray heads in vessels, iv) tanks, filters, and heat  
122 exchangers are more complex than ordinary pipe work is to clean.

123 This paper addresses one of these issues in particular, the formation of sodium  
124 carbonate ( $\text{Na}_2\text{CO}_3$ ) in sodium hydroxide ( $\text{NaOH}$ ) cleaning detergents commonly used  
125 in FMCG process cleaning. This is a common challenge encountered by the brewing  
126 and bio-processing industry in the fermentation process, the fundamental engineering  
127 and chemistry of which is considered by Hikita et al (1976). It is for this reason we  
128 concentrate on fermenter cleaning. Sodium carbonate formation occurs due to the  
129 presence of residual carbon dioxide ( $\text{CO}_2$ ) in vessels as a by-product of fermentation.  
130 Cleaning pre-requisites set maximum  $\text{Na}_2\text{CO}_3$  limits permissible in the detergent which  
131 will potentially result in premature disposal of the detergent with increased costs,  
132 effluent, environmental impact, and water and utility consumption.

133  $\text{Na}_2\text{CO}_3$  is a cleaning agent itself, but its cleaning ability in conjunction with  $\text{NaOH}$  has  
134 not been quantified, neither has there been any investigation as to whether there are any  
135 inhibitory effects on the cleaning ability of  $\text{NaOH}$ . Pre-requisite levels of  $\text{Na}_2\text{CO}_3$  and  
136  $\text{NaOH}$  have been put in place at the brewery considered in the study based on industry

137 generic empirical values provided by external cleaning companies. The strength of the  
138 NaOH within a CIP cycle is measured continuously online using a measure of  
139 conductivity, thus providing feedback information on the chemical cleaning step in  
140 place, and the theoretical quantity of active NaOH present during the detergent step.  
141 The NaOH strength is increased if the level of conductivity is not sufficient.

142 This paper considers a different aspect to previous cleaning studies. Other studies  
143 typified above have concentrated on physical cleaning approaches and their  
144 effectiveness at design levels of operation. This paper addresses how these are impacted  
145 by degradation in the design conditions. There is no available literature on the  
146 recommended limits of the minimum NaOH and maximum Na<sub>2</sub>CO<sub>3</sub> levels, before the  
147 cleaning ability of the solution is reduced to a point where it ceases to clean effectively.  
148 Furthermore, high levels of Na<sub>2</sub>CO<sub>3</sub> and low levels of NaOH may provide a sufficiently  
149 high conductivity reading to provide 'false' feedback information in terms of it  
150 indicating the presence of a theoretically higher quantity of active NaOH. This paper  
151 investigates the cleaning abilities of NaOH and Na<sub>2</sub>CO<sub>3</sub>, measurements required to  
152 assess their concentration and limits to optimise the detergent step in a CIP cycle  
153 thereby improving confidence in cleaning.

154

## 155 **Experimental Approach**

156 (a) Methods - A bench scale cleaning rig was developed to represent 'real life' brewery  
157 cleaning conditions (Figure 1). The rig consisted of a small tank which contained a  
158 4 litre solution of cleaning detergent to be recirculated via peristaltic tubing and a  
159 centrifugal pump into a nozzle which sprayed the solution directly onto a suspended  
160 5cm square stainless steel 316L coupon. The coupon was prepared by taking 5g of  
161 post filtered beer bottoms and spreading it evenly across the surface area leaving a  
162 coating of around  $1\text{g} \pm 0.01\text{g}$  of dried, evenly spread, post filtered beer bottoms. The  
163 soil was allowed to completely dry for two days to complete coupon preparation  
164 under ambient conditions. All coupons were prepared at the same time to minimize  
165 humidity variation impact. The importance of careful and consistent soil sample  
166 preparation was described by Ishiyama et al (2014) and therefore rigorous attention  
167 was placed on soil sample preparation as described above. Beer bottoms were used  
168 as they represented a worst case soil scenario and provided a repeatability not  
169 possible with foam soiling. A bypass valve was used on the peristaltic tubing to  
170 enable variation of flow rate through the cleaning nozzle. The hose nozzle is sprayed  
171 directly onto the top of the fouled coupon to form a waterfall type effect over the  
172 coupon.

173 The design specification of the mini rig was based on scaled down values of the direct  
174 forces and shear forces of fluid falling down the walls from the direct impact of a  
175 cleaning head spray jet with a shear force of at least 3 Pa (the same as that in a large  
176 scale fermenter of 7000hl volume on site (Jensen, 2012)). This involved using flowrates

177 of 50ml/s and 100 ml/s. The jet was directed at an angle of 60° to the coupon at a  
178 distance of 30cm from the coupon. This represents a scaled down mimic of an average  
179 position in the foam line of the tank. The nozzle diameter was 5mm.

180 A full factorial experimental design was undertaken that covered all combinations of  
181 NaOH and Na<sub>2</sub>CO<sub>3</sub> at fixed intervals between 0 and 2% w/v and 0 and 12% w/v  
182 respectively. Cleaning at two different flow rates was also considered and each  
183 combination was performed in triplicate. Table 1 provides details of the design.

184 A total of 90 experimental runs were performed on the rig under ambient temperature  
185 conditions consistent with industrial operation. For each run a fresh 4l solution was  
186 made and recirculated for 30s to ensure that the solution was well mixed. Fresh  
187 solutions for each run ensured that decreased surface tension due to increased quantities  
188 of suspended solids within the solutions did not have an impact on the results. A fouled  
189 coupon was then suspended in the tank and the transparent Perspex lid closed. The  
190 pump was switched on to begin recirculation and the cleaning of the coupon was  
191 observed and timed until the coupon was visibly clean. Images of the coupon were  
192 taken at this point to document the results. Visibly clean was selected as the measure  
193 for cleanliness as the detergent step is used to remove soils and a nitric acid sanitation  
194 step is always performed after the detergent step when cleaning brewery equipment and  
195 is consistent with the approach adopted in the brewery. Approaches to verify the visibly  
196 clean metric were based on the underlying principles found in Nostrand and Forsyth  
197 (2005). If the coupon was not visibly clean by 600s it was assumed that this solution  
198 would not be sufficient to clean the soil, as no area within a vessel would be exposed  
199 to cleaning solution at this force, for this amount of time, in a 'real life' cleaning  
200 scenario.

201 Samples of each solution were taken at the end of each run from the discharge point  
202 and titrated to verify the correct combination of chemicals within the solutions had been  
203 used. pH and conductivity readings were also taken to investigate the relationships  
204 between these measurements and the strength of the individual solution components.  
205 The conductivity probe used was an Omega CDH-280 and the pH meter was a Mettler  
206 Toledo Five Easy FE20. Both were desktop offline probes.

207

208 (b) Results - The table of results is too large to be included in this paper, but the trends  
209 and general interactions between the variables are discussed. A general linear model  
210 was developed using Minitab® 16.2.4 which included the input variables (flow rate,  
211 NaOH concentration and Na<sub>2</sub>CO<sub>3</sub> concentration) and the output variable, cleaning time.  
212 The linear modelling approach is adopted following the good modelling practice  
213 approach that the model should be as simple as possible as long as it is effective. All  
214 input variables were shown to have first and second order interactions and have been  
215 included in the model.

216 Figure 2 shows the interaction plot for the individual variables of NaOH concentration,  
217 Na<sub>2</sub>CO<sub>3</sub> concentration and cleaning time. This shows that if no NaOH is present, then  
218 the detergent generally will not clean, but it will clean slowly with 2-4% Na<sub>2</sub>CO<sub>3</sub>  
219 present, hence water alone will not clean. NaOH >1% will clean well unless the Na<sub>2</sub>CO<sub>3</sub>  
220 level is 12% or more, so Na<sub>2</sub>CO<sub>3</sub> does not inhibit cleaning sufficiently until this point.  
221 However, sodium carbonate levels present at 12% will still clean with a sufficiently  
222 high flow rate. In this figure and subsequent figures the titrations to determine NaOH  
223 and Na<sub>2</sub>CO<sub>3</sub> concentrations result in errors of concentration determination of ±0.15w/v.  
224 The error associated with flowrate measurement is ±2ml/s. The results also show that  
225 there is a strong dependency of cleaning ability on the flow rate, showing that higher  
226 flow rates improve cleaning abilities.

227 Figure 3 shows the contour plot for NaOH concentration and Na<sub>2</sub>CO<sub>3</sub> concentration  
228 based on cleaning time. The blue areas are those that cleaned in the shortest time and  
229 thus are considered to denote the conditions that give the best cleaning. It can be seen  
230 that 1% NaOH and 9% Na<sub>2</sub>CO<sub>3</sub> denote the limits of the fastest cleaning times. These  
231 are denoted by the red dashed lines. The section between 2 and 4% Na<sub>2</sub>CO<sub>3</sub> with less  
232 than 1% NaOH also shows a slight cleaning power of Na<sub>2</sub>CO<sub>3</sub> alone where cleaning is  
233 taking place with no (or little) NaOH present. This section is in a lighter shade of blue  
234 which shows that although it does clean at this strength without the presence of  
235 NaOH. This will not be sufficient to clean the fermentation vessel effectively as the  
236 cleaning time required for cleaning the vessel with this solution will be approximately  
237 three times longer than it is currently. This deems it less cost effective and fails to  
238 satisfy the objective of cleaning detergent cost based optimization where at least  
239 cleaning within the current time frame is the objective.

240

241

242

243 Two further general linear models were developed in Minitab® 16.2.4 based on the  
244 offline measurements of conductivity and H<sup>+</sup> ions which were recorded from each of  
245 the experimental samples.

246 Figure 4 shows the interaction plot for NaOH concentration, Na<sub>2</sub>CO<sub>3</sub> concentration  
247 and conductivity. The error associated with conductivity measurement is ±1.0mS/cm<sup>2</sup>.  
248 It can be seen that 1% NaOH gives a conductivity reading which is the same as  
249 approximately 5% Na<sub>2</sub>CO<sub>3</sub>. Due to this, it is possible that readings from a  
250 conductivity probe will give a false security of detergent specifications. Readings of  
251 NaOH < 1% and Na<sub>2</sub>CO<sub>3</sub> > 5% will appear to be within specification.

252 Figure 5 shows the interaction plots for NaOH concentration, Na<sub>2</sub>CO<sub>3</sub> concentration,  
253 and pH values. The error associated with pH measurement is ±0.008. It can be seen that  
254 samples of only water will have a pH of less than 10. Some water samples have pH

255 values as high as 10 due to residual traces of alkaline remaining in the experimental rig  
256 pipework from previous runs. Solutions of  $\text{Na}_2\text{CO}_3$  alone will have a pH of  
257 approximately 12 and NaOH solutions will have a pH of approximately 13. When  
258 combined solutions of NaOH and  $\text{Na}_2\text{CO}_3$  are present which contain more than 1%  
259 NaOH, the pH of NaOH appears to dominate the overall pH, resulting in a pH of 13-  
260 13.5. This is due to the reduction of dissociation of  $\text{H}^+$  ions within the solution based  
261 on the hydroxide and carbonate ions together, resulting in a higher pH when NaOH is  
262 present. This shows that the use of a pH probe will enable the determination of the  
263 presence of NaOH or  $\text{Na}_2\text{CO}_3$ .

## 264 Discussion

265 (a) Chemical Limits - The investigation based on the chemical concentrations within  
266 the cleaning detergent has shown that NaOH needs to be at least 1% w/v for the clean  
267 to be effective. NaOH concentrations greater than 1% make no significant  
268 improvements in terms of the cleaning abilities demonstrating that it is not cost  
269 effective to clean in industry with NaOH strengths of greater than 1% w/v as there is  
270 no additional cleaning benefit.

271  $\text{Na}_2\text{CO}_3$  has been shown to have a cleaning ability on brewery soils between 2-4% w/v  
272 but is not sufficient for cleaning brewery equipment as a sole detergent. Increasing  
273 concentrations of  $\text{Na}_2\text{CO}_3$  appear to inhibit the cleaning abilities of NaOH slightly, but  
274 not enough to prevent sufficient cleaning until concentrations of greater than 9%.  
275 Although concentrations of  $\text{Na}_2\text{CO}_3$  up to 9% will have some impact on cleaning  
276 abilities, it will be most cost effective to allow the strength to reach 9% before replacing  
277 the detergent as cleaning will still be effective enough to visibly clean a worst case  
278 scenario brewery soil up until this point.

279 Cleaning flow rate is important when cleaning and this has been verified in the work of  
280 Goode et al (2010). Industrial cleaning with higher flow rates will enable a higher  
281  $\text{Na}_2\text{CO}_3$  limit to be put in place and the cleaning detergent to be replaced less frequently.  
282 It is necessary to ensure that the process can consistently achieve the required flow rate  
283 when cleaning all equipment before selecting a higher  $\text{Na}_2\text{CO}_3$  limit. If the minimum  
284 flow/pressure requirements specified by the cleaning head manufacturers are not  
285 reached then the  $\text{Na}_2\text{CO}_3$  levels will have more of an impact on the NaOH cleaning at  
286 lower levels.

287 The recommended chemical limits within the detergent cleaning step at the minimum  
288 required flow conditions are  $\text{NaOH} > 1\%$  w/v and  $\text{Na}_2\text{CO}_3 < 9\%$  w/v. Implementation  
289 of these limits on one of Heineken's sites will yield an estimated 56% chemical cost  
290 saving. This value was determined by performing industrial cost benchmark analysis,  
291 adopting the techniques developed by Ahmad and Benson (2000) and through analysis  
292 of cleaning data that is commercially sensitive although but the underlying principles  
293 of Ahmad and Benson cover generic application and transferability of the methods  
294 discussed.

295 (b) Online Measurements - The use of conductivity alone as an industrial method of  
296 online measurement of the active NaOH concentration present within the detergent is  
297 not effective when continuous dosing of NaOH is applied. There is typically more than  
298 700 hl of residual CO<sub>2</sub> from the 10% headspace of a 7000 hl fermentation vessel. This  
299 is more than sufficient to achieve high levels of Na<sub>2</sub>CO<sub>3</sub> when continuous NaOH  
300 dosing. If more than 5% Na<sub>2</sub>CO<sub>3</sub> is present it will show that the conductivity is  
301 sufficiently high when insufficient NaOH is present due to the conductivity associated  
302 with Na<sub>2</sub>CO<sub>3</sub>. This is not a suitable industrial method as incorrect indications of NaOH  
303 levels will result in ineffective cleaning which may have an impact on microbial growth  
304 within the equipment, resulting in spoilage of product and additional costs to the  
305 company. Conductivity does give an indication of the quantity of ions present and can  
306 be used in conjunction with further information to provide a better indication of the  
307 detergent chemical concentrations.

308 An online pH probe will provide information on the minimum strengths of NaOH and  
309 Na<sub>2</sub>CO<sub>3</sub> present. Combining this information with the online conductivity information  
310 by data fusion will enable confidence that at least 1% NaOH is present and an indication  
311 of when Na<sub>2</sub>CO<sub>3</sub> strength is increasing. It is sufficient to consider both signals together  
312 but conductivity or pH alone is not informative. Additional flow monitoring of any  
313 NaOH added to the detergent will be required to ensure that concentrations of Na<sub>2</sub>CO<sub>3</sub>  
314 in excess of 9% may not be achieved. Using this method will provide operational  
315 confidence and ensure that cleaning is being performed to an acceptable standard  
316 throughout the full duration of the detergent cleaning step.

317 Implementation of the determined chemical limits within the detergent, and application  
318 of a cost optimisation technique incorporating the data fusion of pH, conductivity, and  
319 flow monitoring of concentrated NaOH will provide cost savings on one Heineken site  
320 of 56% in cleaning chemical costs, which contributes to 10% of total cleaning costs on  
321 the fermentation vessels. The resulting operational savings provide a payback time on  
322 capital investment by the business for this change of less than eight months.

## 323 **Conclusions**

324 This paper has considered the degradation of NaOH during the cleaning of brewery  
325 process equipment. It was known previously that Na<sub>2</sub>CO<sub>3</sub> formation degraded cleaning  
326 ability and this paper has quantified the extent of this loss of performance. This  
327 quantification has enabled a more informed and optimised CIP strategy to be  
328 implemented in brewery operations. To do so requires additional on-line measurements  
329 to be made to distinguish between NaOH and Na<sub>2</sub>CO<sub>3</sub> compositions. It has been shown  
330 that with measures of pH and conductivity of the cleaning fluid it is possible to gain  
331 this information and consequently be able to determine the current cleaning capability.

332 Considering future work the prime activity is to assess long term returns to ensure that  
333 short term gains are maintained before technology 'roll out' to other Heineken sites.  
334 Further technical studies also follow in from this work such as the impact of Toftejorg

335 spray head interruptions throughout cleaning procedures to quantify the inhibition to  
336 the ability of cleaning the complete surface area with the standard that has been set out  
337 by the cleaning head manufacturers. Methods to deal with problem root cause are also  
338 worthy of exploration such as the removal of carbon dioxide through nitrogen purging  
339 or alternative cleaning detergents which will not react with carbon dioxide for a long  
340 term cost effective solution. On the installation of a brand new CIP set, these would be  
341 the more cost effective options by removing the root cause of the carbonation formation  
342 but for existing equipment costs are prohibitive.

### 343 **Acknowledgements**

344 The research in this paper was undertaken through the Engineering Doctorate  
345 programme funded by the Engineering and Physical Sciences Research Council, grant  
346 number EP/G018502/1 and Heineken. The authors would also like to thank Johnson
